

# Principles and science of stocking sea cucumbers into the wild

Steven Purcell  
National Marine Science Centre  
Southern Cross University, Australia

## Presentation overview

- Invertebrate stocking: a new era
- Scales of release, different methods and timeframes
- Preserving the integrity of wild stocks
- The dangers of translocation
- Disease screening
- Chemical marking of cultured juveniles
- Use of sea pens
- Surveys to assess the success of sea ranching and restocking
- Likely economic returns ?
- Conclusions

# Stocking of invertebrates

- Scallops
- Abalone
- Queen Conch
- Shrimp
- Crayfish and Lobsters
- Sea Urchins
- Giant Clams
- Topshell (Trochus)
- Sea Cucumbers

## Jumping in too early

Why did enhancement programs have such poor success?

- Restocking and sea ranching are relatively new fields
  - Enhancement activities were driven by the ability to produce juveniles  
But...
    1. Goals ?
    2. Cost \$\$\$ !!
    3. Predation?, habitat requirements?, post-release movement?
    4. Animals were rarely marked to prove the success of captive-release
- Poor success in many case studies gave a bad name to stock enhancement and restocking

## Marine stocking - a 'new era'

Bartley and Bell (2008) – *Rev. Fisheries Sci.*

- Challenges in this 'new era' of stocking include the need to:
  - critically assess costs and benefits,
  - conduct research to work out how to release animals so they survive well, and
  - use science to prove the cost-effectiveness of stocking

# Sea cucumber management and the role of restocking and sea ranching

- Stock Enhancement
  - Increasing stocks and commercial harvests in an existing fishery
- Restocking
  - Restoring breeding populations in a depleted fishery
- Sea Ranching
  - Growing shellfish in an open area defined by a lease or through property rights
- Sea Farming
  - Growing marine organisms in a bounded space – e.g. a fenced off area or in a pond or embayment

Definitions: see Bell et al. (2005, Adv. Mar. Biol.) and Bell et al. (2008, Rev. Fish. Sci.)

# Scales of release

## ***Stock Enhancement***

- Mass release at low density into broad areas

## ***Restocking***

- Moderate-scale release at moderate to high density in relatively small areas

## ***Sea Ranching***

- Release at high density into restricted areas

## ***Sea Farming***

- Release at very high density

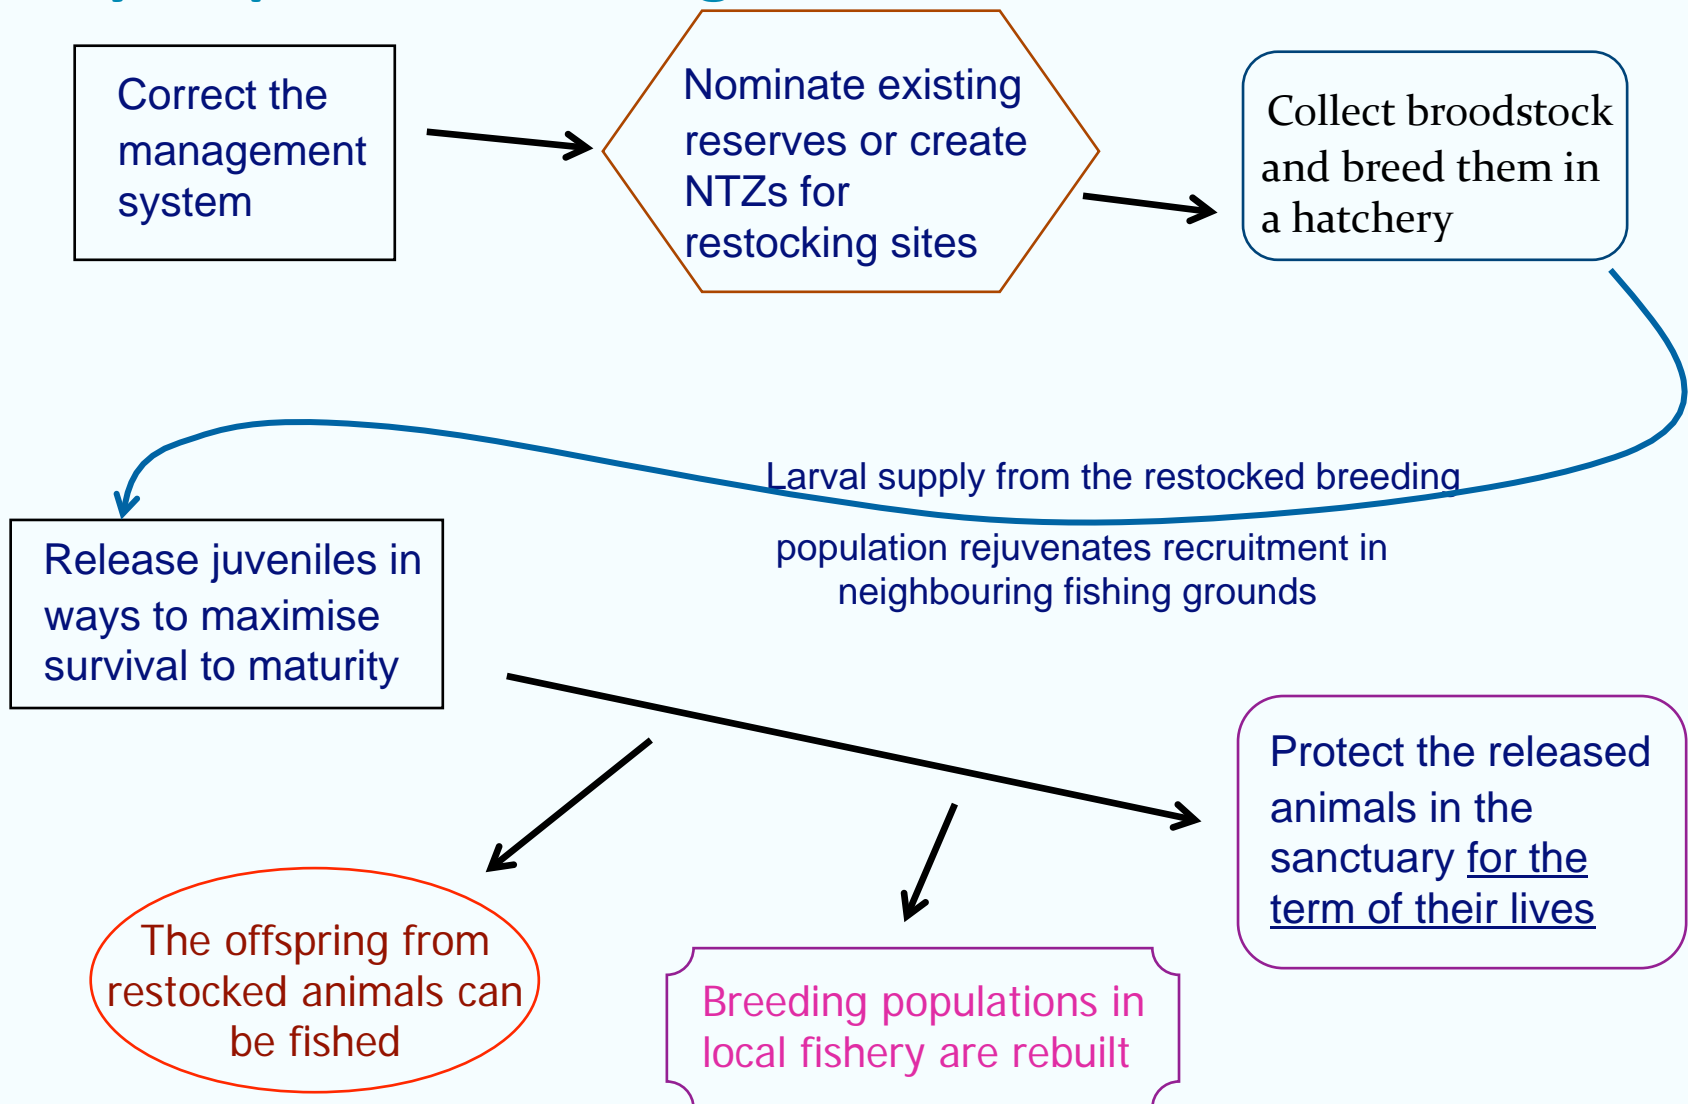

## Restocking – 7 golden rules

1. It is a management tool - analogous to 'captive release' programs
2. Applicable when there are so few animals that you can't form effective breeding populations by aggregating remnant animals in the fishery
3. Survival will be poor unless the release methods are determined and used
4. The released animals must be protected as a nucleus breeding population
5. The protected area (sanctuary/reserve/NTZ) is big enough so that the majority of animals don't move out of it into grounds where they can be fished
6. At maturity, the animals are in high enough densities to find each other easily to allow successful natural breeding
7. The restocked breeding population is sited such that their offspring can settle in areas within the target fishery

## Key steps of restocking

## Sea Ranching – 7 precepts

1. It is an extension of aquaculture - “put, grow, and take”
2. Beneficiaries have full property and access rights
3. Like restocking, the release methods are well founded to give good survival
4. Most animals need to remain inside leased/managed area
5. Harvest efficiency will be high – poaching is minimal and animals can be easily harvested
6. Animals are harvested at a size that maximises economic returns per released juvenile
7. Success = the money made from harvesting the animals far outweighs the cost of producing juveniles

Was more money earned from sea ranching than could have been gained from banking the money to produce/buy juveniles and earning the interest? or investing it in other aquaculture/fisheries initiatives?

## Key steps of sea ranching

Gain access rights over an area of optimal habitat for releasing and growing the animals

Produce juveniles in a hatchery or buy them

Release juveniles in ways to maximise survival to maturity

Protect the released animals in the area until they reach an optimum market size

Harvest all animals

Improved recruitment to neighbouring fishing grounds is a secondary effect

# Preserving the integrity of wild stocks

- Wild stocks will be needed in future:
  - Broodstock for producing juveniles in hatcheries
  - Rebuilding healthy wild populations resilient to disease, natural disasters, other natural and human-induced disturbances
- This relies on us to:
  - Ensure the **genetic diversity** and genetic structure of each population is not compromised
  - Ensure we don't introduce, or increase the prevalence of, **disease** into wild populations

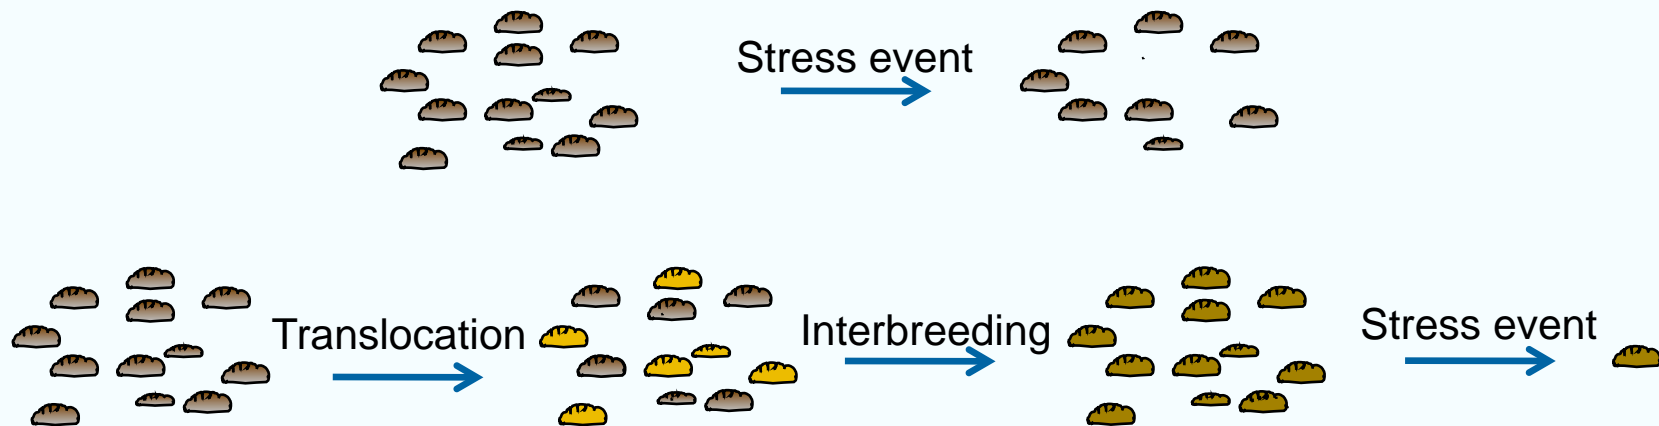

# Potential problems from translocation

- Can reduce genetic diversity of wild stocks:
  - 'Introgression' - introduction of foreign alleles
    1. Interbreeding of introduced stock with wild stock
    2. Out competing native alleles
  - Introgression reduces the genetic identity of stocks and the unique (and potentially advantageous) genetic composition of native stocks

# Potential problems from translocation

- 'Outbreeding depression' can occur from interbreeding of introduced stock with native stock
  - Disturbs adaptations native stock have to local environment

- Interbreeding of translocated stock have been shown to have long-lasting effects, that tend to be disadvantageous in the long term rather than beneficial
- Translocation problems are more of a risk with species that have limited larval dispersal – e.g. *Holothuria scabra*

# Limited gene flow and larval dispersal of sandfish

- On regional scale, genetic differences related to geographic distance
- Restricted gene flow in sandfish at scales <100 km

## Lesson for restocking and sea ranching

- Juveniles should only be translocated near to the natal sites (where broodstock parents were collected)
- Juveniles cultured from broodstock in one country should NOT be shipped to another country

Uthicke and Purcell (2004) – *Can. J. Fish Aquatic Sci.*

**Preservation of genetic diversity in restocking of the sea cucumber *Holothuria scabra* investigated by allozyme electrophoresis**

Sven Uthicke and Steven Purcell

**Abstract:** Population genetics analyses should be considered when releasing hatchery-produced juveniles of the sea cucumber *Holothuria scabra* when spawning from isolated populations are used in New Caledonia. Allozyme genetic heterogeneity of *H. scabra* populations (examined through allozyme electrophoresis of 258 animals) indicated high gene flow between some sites and  $F_{ST}$  values did not deviate significantly from zero. However, most tests indicated that populations at two sites with limited water exchange in the southern locations were significantly different from populations at three other locations on the west coast. Isolation of *H. scabra* sampled in Bali ( $n = 96$ ) and Koroor Bay, Australia ( $n = 47$ ), and comparisons with existing data from the west Pacific (Tasman Strait, Solomon Islands, Upou Bay, Harvey Bay) showed that populations were significantly different (using exact tests) and samples partitioned distinctly using unweighted pair group method with arithmetic mean clustering. Bayesian genetic distance values between populations were significantly related to geographic distances, showing a pattern of isolation by distance. The rapid increase in genetic distance over the first few hundred kilometres supports the view that the spatial extent of any translocation needs to be carefully considered on the basis of knowledge of variation in allele frequencies within the target area.

**Résumé:** Lorsqu'on introduit en nature des jeunes *Holothuria scabra* élevés en pisciculture et issus de parents qui n'appartiennent pas aux populations locales, il est indiqué de penser à des analyses génétiques de population. En Nouvelle-Calédonie, l'hétérogénéité génétique des populations de *H. scabra* au sein d'un même régime (basée sur l'examen par électrophorèse des allèles de 258 individus) démontre l'existence d'un important flux génétique entre deux sites, de plus, les valeurs de  $F_{ST}$  ne diffèrent pas significativement de zéro. Cependant, des tests précis montrent que les populations à deux sites du sud, qui font peu d'échange d'eau, diffèrent significativement de trois autres populations de la côte occidentale. L'isolement de spécimens de *H. scabra* prélevés à Bali ( $n = 96$ ) et à la baie Koroor en Australie ( $n = 47$ ), de valeurs qui la comparaison avec les données existantes pour le Pacifique occidental (détroit de Tasman, les Salomon, baie Upou et baie Harvey), indiquent que les populations sont significativement distinctes (à l'aide de tests exacts) et que les échantillons se segmentent de façon nette dans une analyse de regroupement de type UPGMA. (méthode de regroupement par association moyennée UPGMA). Les valeurs de distance génétique de Bayes entre les populations sont en corrélation significative avec les distances géographiques, ce qui indique un système d'isolement par la distance. L'augmentation rapide de la distance génétique sur les premières centaines de kilomètres appuie l'opinion que la répartition spatiale de toute translocation doit être prise en compte soigneusement à partir de ce qu'on connaît de la variation dans les fréquences d'allèles dans la région cible.

**Introduction**

About 20 species of sea cucumbers of the order Aspidurochele are fished commercially in the tropical Indo-Pacific. The processed body wall, known as "beche-de-mer" or "sea slug", is exported to Asia, where it is consumed as a delicacy, or a natural medicine. Fuelled by an insatiable demand for this species, there is some evidence that natural recovery of sea cucumber stocks may take several

plated stocks of commercially important species (Connell 1997, 2001; Uthicke and Thorne 2000).

The species of highest value, the sandfish *Holothuria scabra*, is overfished in many regions because it often occurs in easily accessible, shallow coastal waters (Connell 1999; Hines et al. 2001). Although countries such as Australia, Fiji, and the Solomon Islands have imposed long-term fishery closures for this species, there is some evidence that natural recovery of sea cucumber stocks may take several

# Minimising introduction of diseases

Perform a simple visual disease check in your own hatchery, using established protocols

## An external check for disease and health of hatchery-produced sea cucumbers

Steven Purcell<sup>1</sup> and Igor Eeckhaut<sup>2</sup>

### Abstract

Sea cucumber diseases that arise in the hatchery can cripple production and undermine restocking programmes. A rapid protocol for the external examination of juvenile sea cucumbers was developed in order to screen for disease and poor health. After selecting a random sample of juveniles from the entire group, each individual is examined for one minute under low-power microscopy. Six external criteria are checked, including abnormalities of the mouth, anus, papillae, body colour, and signs of excess mucus, unhealed lesions, parasites and macroassociates. If more than 5% of screened animals were "unhealthy" or more than 2% were "diseased", then the whole group from which the sample was derived should be considered unfit for grow-out or restocking. In such cases, the handling and environmental conditions in the hatchery should be improved and the entire group quarantined and treated. The protocol sets a standardised procedure for checking large numbers of juveniles for many infectious diseases, and is a starting point for further development of standardised protocols.

### Introduction

Production of hatchery-reared sea cucumbers has gained global interest, and is underway in Australia, China, Ecuador, Kiribati, Madagascar, Malaysia, New Caledonia and Vietnam. Regardless of whether juveniles are to be used for restocking, stock enhancement or land-based grow-out, diseases can arise in the hatchery and cripple production. Identifying diseases in the hatchery is a precondition for their treatment and a prerequisite for releasing juveniles into the wild. Until recently, however, little was known about sea cucumber diseases.

Diseases can be biomolecular (e.g. hereditary), induced by pathogens, or arise from abiotic factors (Kinne 1980). The United Nations-FAO funded workshop in China (October 2003), "Advances in Sea Cucumber Aquaculture and Management", improved the collective knowledge of biotic diseases and parasites affecting sea cucumbers. Wang et al. (2004) reported that various pathogens, including bacteria, fungi and other parasites, could affect *Apostichopus japonicus* larvae and juveniles in culture conditions. Clinical signs of infections include lesions starting around the mouth or anus, whitish ulcerations on the skin or papillae, excessive mucus on the body, skin discoloration, and changes in behaviour and appearance (e.g. the infected animals can become thin, weak and sluggish). Eeckhaut et al. (2004) provided a list of bacteria, protozoans and metazoans (e.g. flatworms, gastropods and crustacean parasites) that can potentially cause disease in sea cucumbers. They also

reported a contagious bacterial disease of *Holothuria scabra* that begins as a white lesion close to the anus, followed by a lesion that progresses quickly over the body. Microscopy and biomolecular techniques have proved instrumental in identifying the bacterial species associated with that disease, called "skin ulceration disease" (Becker et al. 2004). Symptoms of many of the diseases reported by Wang et al. (2004) and Eeckhaut et al. (2004) can be seen externally by low-power microscopy so it should be possible to screen juveniles for visible symptoms of diseases prior to transfer to grow-out ponds or into the wild.

Aside from true biotic diseases, some sea cucumber illnesses can be viral, chemical or from poor culture environment. For example, excess aeration or inappropriate temperatures cause illness and death in sea cucumber larvae (Hamel et al. 2001; Wang et al. 2004). In New Caledonia, copper wire placed in tanks was sufficient to kill juveniles within days (S. Purcell, unpubl. data). Illnesses may be subtle with no lesion or malformation. Instead, the animals become unhealthy and the symptoms could include sluggishness or change in body colour. Illness from chemical contamination could reduce feeding in juveniles and make them more prone to predation when they are released into the wild.

The impacts of releasing diseased or unhealthy juveniles into the wild can be indirect or direct. First, contagious diseases from hatchery-reared sea cucumbers can spread to native stocks, competitors or predators. For example, some bacterial strains can be infectious to other invertebrates

Anus

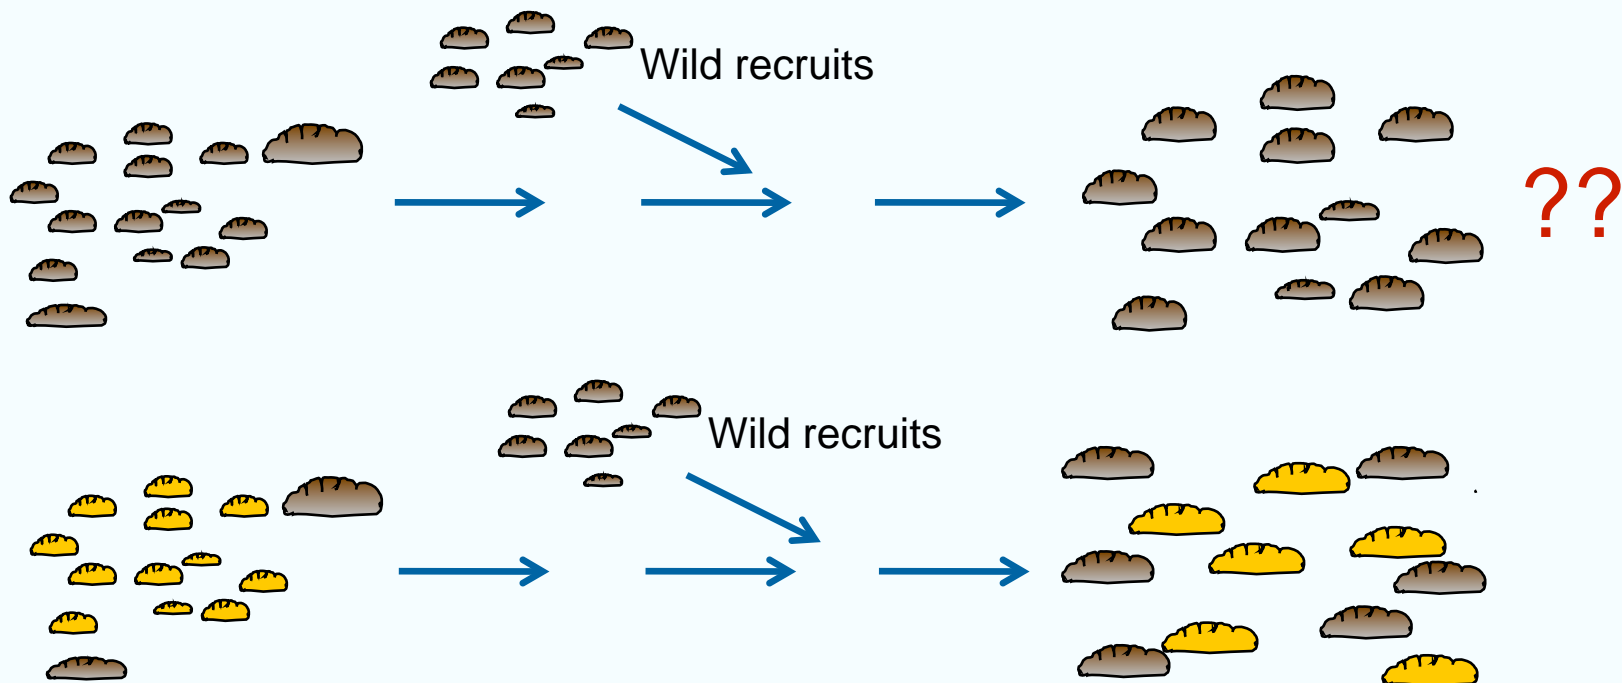

Lesions?  
Discoloration?  
External parasites?  
White spots or fluffy patches?  
Excessive mucus?

# Why should we need to mark or tag cultured juveniles?

1. To be able to assess the survival rate of released juveniles  $\Rightarrow \Rightarrow$  cost effectiveness?
2. To show that the animals we later harvest came from the animals we released
  - Provides proof of stock ownership

# Chemical marking fluorescently colours sea cucumber spicules

## Spicules ('ossicles')

- In the outer body wall – mainly in the dermis
- Calcareous
- Very small (less than 1/10<sup>th</sup> of a mm!)
- Produced as the animal grows

## Fluorochromes

- **Tetracycline (and oxytetracycline)**
- **Calcein**
- **Calcein blue**
- **Xylenol orange**

# Chemical marking with flurochromes

- The juveniles must be in a period of active growth before immersion marking

Keeping juveniles in a bare tank overnight

Fluorochrome stock solution added to tank with aerated seawater and heater

Tanks shaded and animals left in immersion solution for 24 h

## Marker verification - sampling

Taking a sample of outer body wall  
and bring back to the lab

Digest soft tissue in bleach to  
get cleaned spicules

Check spicules to see if any are  
marked with a fluorochrome

# Marked spicules under fluorescent microscope

White light only

Spicules marked with tetracycline (T) and calcein (C) sequentially

UV light only

Xylenol orange

Calcein blue

# Sea pens – an experimental tool

Gauging the post-release survival of juvenile sea cucumbers: A dilemma

# Small sea pens

- Small sea pens (1 m<sup>2</sup> to 10 m<sup>2</sup>) are great for short-term work
- Chance of escapement increases with smaller pens
- A netting skirt at the top of the pen significantly reduces escapement

## Large sea pens

- Pens need to be open to replicate the natural conditions – so that we can assume similar mortality in and out of the pens
- A strip of antifouling on the mesh should reduce escapement
- Big pens (100-1000 m<sup>2</sup>) are harder to install
- 500 m<sup>2</sup> pen – 2 days to install 3 pens
- Pens are difficult to set up in firm sand – muddy sand is best for sandfish

# Field surveys to assess the success of stocking

## QUADRAT SURVEYS IN SEA PENS

- Quadrats need to be set randomly – in pre-determined positions
- Need to assess border separately
  - This requires stratified sampling

## Assessing the success of sea ranching

- Release the marked juveniles into a core area in a natural habitat
- Allow 1 year for them to attain a size at which they can be seen in surveys
- Assess survival of larger sandfish by using transect surveys within dispersion zones and verifying the origin of the animals using analysis of their spicules

Juveniles are expected to move further if the habitat is sub-optimal

Random transects  
for visual surveys

## Survival of released juveniles?

- Most of the mortality occurred in the first couple months after release
- At some sites, none of the released animals survived to market size

Experiment 1

Experiment 2

Purcell & Simutoga (2008) – Rev. Fisheries Sci.

- If animals are released in the correct habitats, at initial sizes of >3 to 10 g, **survival to market size** (700 g) was predicted to be **7-20%**
- Survival may be higher at other localities where predators are removed or where the animals can grow to adulthood faster

## Likely economic returns from sea ranching?

A quick calculation:

- Conservatively, **one-in-ten animals** will survive to market size

Total cost per juvenile (3-10 g) of production, release and harvest must be **US 24 cents or cheaper**, just to break even

Maybe you only find 80% of those that survived

1 adult of 700 g = about US\$3

# Lessons for sea ranching and restocking

## Unpredictability

- Factors beyond those controllable by optimal release strategies can dictate success (e.g., cyclones, predator invasion, flooding)
  - Success on one occasion doesn't guarantee success at that site on another occasion
  - Success from short-term experiments is no guarantee for success of large-scale releases over longer time frames – some key causes of mortality occur infrequently
- Plan on some sites failing – use multiple release sites and multiple times

## Lessons for sea ranching and restocking

1. Firstly determine the optimal **habitats**, **sizes** and **densities** to release juveniles..
2. **Risks** to wild populations (genetic, disease) are real, and should be **minimised**.
3. **Chemical marking** of juveniles is cheap and simple. Restocking and sea ranching programs should mark all cultured juveniles to prove cost-effectiveness.
4. A **majority** of the **juveniles** you release in the wild **will die or be eaten** by predators before they reach market size.
5. **Sea pens** can help assess survival, and visual surveys can be used once the animals are adults.
6. Juveniles need to be produced **cheaply** for cost effectiveness.
7. Weigh up the **costs** and expected **benefits**, and be aware of the timeframes.
8. Sociological issues and constraints will be just as important as biological ones!
